ABSTRACT

Urethral calculi are rare and represent 1-2% of all urinary stone diseases. Rarely, calculus grows to large size and are labeled as a "giant urethral calculus". A 75-year-old male came to the OPD of Madinah Teaching Hospital Faisalabad with a chief complaint of suprapubic pain, penile pain, and hard mass on the left side of the scrotum and anterior perineum. The patient had a significant history of undergoing debridement for Meleney's and Fournier's gangrene, along with suprapubic cystostomy done about 1.5 years back. Physical examination revealed a solid mass with dimensions 6x7 cm on the left side of the scrotum and anterior perineum (left periurethral area). Open surgery was performed. A huge stone, 6x6cm, was removed. Diverticulae were excised, and urethroplasty was performed. A catheter was removed on the 21st postoperative with a satisfactory urinary stream.

INTRODUCTION

The incidence of urethral calculus is < 1% and is more common in males [1]. The most common predisposing factors for urethral calculus are stricture urethra, urethral diverticulum, recurrent urinary tract infection, foreign bodies within the urinary tract, and previous surgery on the lower urinary tract [2]. Most of the urethral calculi are formed in the kidney or bladder [3,4]. Most of these calculi are struvite, calcium phosphate, or calcium carbonate stones [3]. Urethral calculus cause dysuria, suprapubic pain, weak urinary stream, urinary tract irritation, acute urinary retention and urethra-cutaneous fistula. Giant urethral calculus is a very rare disease and may be associated with urethral stricture or diverticulum. Open surgery is a conventional approach associated with the risk of urinary tract infections, stenosis and urinary fistulae.

CASE

A 75-year-old male presented to OPD with suprapubic pain, penile pain and feeling of hard mass in perineum posterior the left side of scrotum. These symptoms had started 2 years back and had increased in intensity in the last 15 days. The patient also had a significant history of undergoing debridement for Meleney's and Fournier's gangrene along with suprapubic cystostomy done 1.5 years back with no history of the passage of urine perurethra since then.

Physical examination showed a significant lower abdominal scar extending over the left side of scrotum with an inserted suprapubic cystostomy. On palpation, a mass of 6x7 cm was identified posterior to the left side of the scrotum. It was mildly tender. There were no signs of local inflammation. The overlying skin was not separately mobile. Blood parameters, biochemical, coagulation profiles were in a normal range. Urine culture were negative for any growth. X-rays KUB and pelvis, retrograde and antegrade urethrogram before the procedures (Figure: I-II) showed multiple vesicle calculi and a large calculus in the area of the bulbar part of the urethra. On urethroscopy, the distal penile urethra had a pinhole stricture of about 01 cm (internal urethrotomy was carried out). On cystoscopy, three vesicle calculi of about 3x2cm, 2x2 cm and 2x1cm were found, and cystolitholapaxy was done. Urethral diverticular calculus extraction was conducted by open surgery, and urethroplasty was performed. The dimensions of the stone were 6x6 cm (Figure-III). A 16 Fr foley catheter was introduced per-urethrally, which was removed on 21st day with satisfactory stream (Figure: IV-V).

DISCUSSION

Giant urethral calculi are rare. Prevalence is high in developing countries [1]. Males are more commonly affected, although few cases have been reported in females and children [2]. Predisposition factors are diverticulum of urethra, stricture, meatal stenosis with or without hypospadias. Mostly these calculi are struvite [3].

Primary calculi are associated with abnormalities like urethral stricture, a foreign body within the urethra or urethral diverticulae. Stones in the urethra with prolonged stay may lead to local necrosis and fibrosis, which is a probable etiology of diverticulum formation. Secondary calculi have originated in the kidney or bladder. Primary calculi rarely cause acute symptoms, while secondary calculi can cause dysuria, urine retention, straining during voiding, or even sepsis. The most common treatment modality of giant calculus in the urethral diverticulum is open surgery. However, with advancements in technology, endoscopic treatment techniques are becoming more popular. Urethral lithotripsy has been successfully performed with a success rate of almost 100%. For emptied urethral diverticulum, diverticulum resection and urethroplasty is usually performed. After endoscopic calculus removal, several conservative treatments like urethral massage and antibiotics for a longer period have to be advised to the patients. In our case, the urethral diverticulum involved bulbous urethra. After removing calculus, the diverticulum was excised, and urethroplasty was performed with a satisfactory outcome.
